- "Distribution free" methods require fewer assumptions than parametric methods
- Focus on testing rather than estimation
- Not sensitive to outlying observations
- Especially useful for cruder data (like ranks)
- "Throws away" some of the information in the data
- May be less powerful than parametric counterparts, when the parametric assumptions are true
- For large samples, are equally efficient to parametric counterparts

### Alternatives to the paired t-test

- Let  $D_i = \text{difference} (P SR)$
- Let  $\theta$  be the population median of the  $D_i$
- $H_0: \theta = 0$  versus  $H_a: \theta \neq 0$  (or > or <)
- Notice that  $\theta = 0$  iff p = P(D > 0) = .5
- Let X be the number of times D > 0
  - X is then binomial(n, p)
- The sign test tests wether  $H_0: p = .5$  using X

- $H_0: \theta = 0$  versus  $H_a: \theta \neq 0$
- Number of instances where the difference is bigger than 0 is 15 out of 25 trials
- binom.test(15, 25)

p-value = 0.4244

Or we could have used large sample tests for a binomial proportion prop.test(15, 25, p = .5)
 X-squared = 0.64, df = 1, p-value = 0.4237

### • Magnitude of the differences is discarded

- Perhaps too much information lost
- Could easily have tested H<sub>0</sub>: θ = θ<sub>0</sub> by calculating the number of times D > θ<sub>0</sub> and performing a binomial test
  - We can invert these tests to get a distribution free confidence interval for the median

### Signed rank test

- Wilcoxon's statistic uses the information in the **signed ranks** of the differences
- Saves some of the information regarding the magnitude of the differences
- Still tests  $H_0: \theta = 0$  versus the three alternatives
- Appropriately normalized, the test statistic follows a normal distribution
- Also the exact small sample distribution of the signed rank statistic is known (if there are no ties)

## Signed rank procedure

- 1 Take the paired differences
- 2 Take the absolute values of the differences
- 8 Rank these absolute values, throwing out the 0s
- Multiply the ranks by the sign of the difference (+1 for a positive difference and -1 for a negative difference)
- **5** Cacluate the rank sum  $W_+$  of the positive ranks

## Signed rank procedure

▲ロト ▲帰 ト ▲ ヨ ト ▲ ヨ ト ・ ヨ ・ の Q ()

- If  $\theta > 0$  then  $W_+$  should be large
- If  $\theta < 0$  then  $W_+$  should be small
- Properly normalized,  $W_+$  follows a large sample normal distribution
- For small sample sizes,  $W_+$  has an exact distribution under the null hypothesis
- Can get critical values from tables in the textbook

- Assume no ties
- Simulate *n* observations from any distribution that has  $\theta = 0$  as its median
- Rank the absolute value of the data, retain the signs, calculate the signed rank statistic
- Apply this procedure over and over, the proportion of time that the observed test statistic is larger or smaller (depending on the hypothesis) is a Monte Carlo approximation to the P-value

- Here's a slightly more elegant way to simulate from the null distribution
- Consider the ranks 1, ..., n
- Randomly assign the signs as binary with probability .5 of being positive and .5 of being negative
- Calculate the signed rank statistic

### Large sample distribution of $W_+$

- Under  $H_0$  and if there are no ties
  - $E(W_+) = n(n+1)/4$
  - $Var(W_+) = n(n+1)(2n+1)/24$
  - $TS = \{W_+ E(W_+)\}/Sd(W_+) \rightarrow Normal(0,1)$
- There is a correction term necessary for ties
- Without ties, it's possible to do an exact (small sample) test

## The Mann/Whitney test

- Tests whether or not the two treatments have the same location
- Assumes independent identically distributed errors, not necessarily normal
- Null hypothesis can also be written more generally as a stochastic shift for two arbitrary distributions
- Test uses the sum of the ranks obtained by discarding the treatment labels

- Let W be the sum of the ranks for the first treatment (A)
- Let  $n_A$  and  $n_B$  be the sample sizes
- Then

• 
$$E(W) = n_A(n_A + n_B + 1)/2$$

- $Var(W) = n_A n_B (n_A + n_B + 1)/12$
- $TS = \{W E(W)\}/Sd(W) \to N(0,1)$
- Also the exact distribution of W can be calculated

### Example

- W = 51
- E(W) = 8(8 + 13 + 1)/2 = 88
- $Sd(W) = \sqrt{8 \times 13(8 + 13 + 1)/12} = 13.8$
- TS = (51 88)/13.8 = -2.68
- Two-sided P-value= .007
- R function wilcox.test will perform the test

- Note that under  $H_0$ , the two groups are **exchangeable**
- Therefore, any allocation of the ranks between the two groups is equally likely
- Procedure: Take the ranks  $1, \ldots, N_A + N_B$  and permute them
- Take the first N<sub>A</sub> ranks and allocate them to Group A; allocate the remainder to Group B
- Calculate the test statistic
- Repeat this process over and over; the proportion of times the test statistic is larger or smaller (depending on the alternative) than the observed value is an exact P-value

### Notes about nonpar tests

- Tend to be more robust to outliers than parametric counterparts
- Do not require normality assumptions
- Usually have exact small-sample versions
- Are often based on ranks rather than the raw data
- Loss in power over parametric counterparts is often not bad

### Permutation tests

- Permutation tests are similar to the rank-sum tests, though they use the actual data rather than the ranks
- That is, consider the null hypothesis that the distribution of the observations from each group is the same
- Then, the group labels are irrelevant
- We then discard the group levels and permute the combined data
- Split the permuted data into two groups with n<sub>A</sub> and n<sub>B</sub> observations (say by always treating the first n<sub>A</sub> observations as the first group)
- Evaluate the probability of getting a statistic as large or large than the one observed
- An example statistic would be the difference in the averages between the two groups; one could also use a t-statistic

- This is an easy way to produce a null distribution for a test of equal distributions
- Similar in flavor to the bootstrap
- This procedure produces an exact test
- Less robust, but more powerful than the rank sum tests
